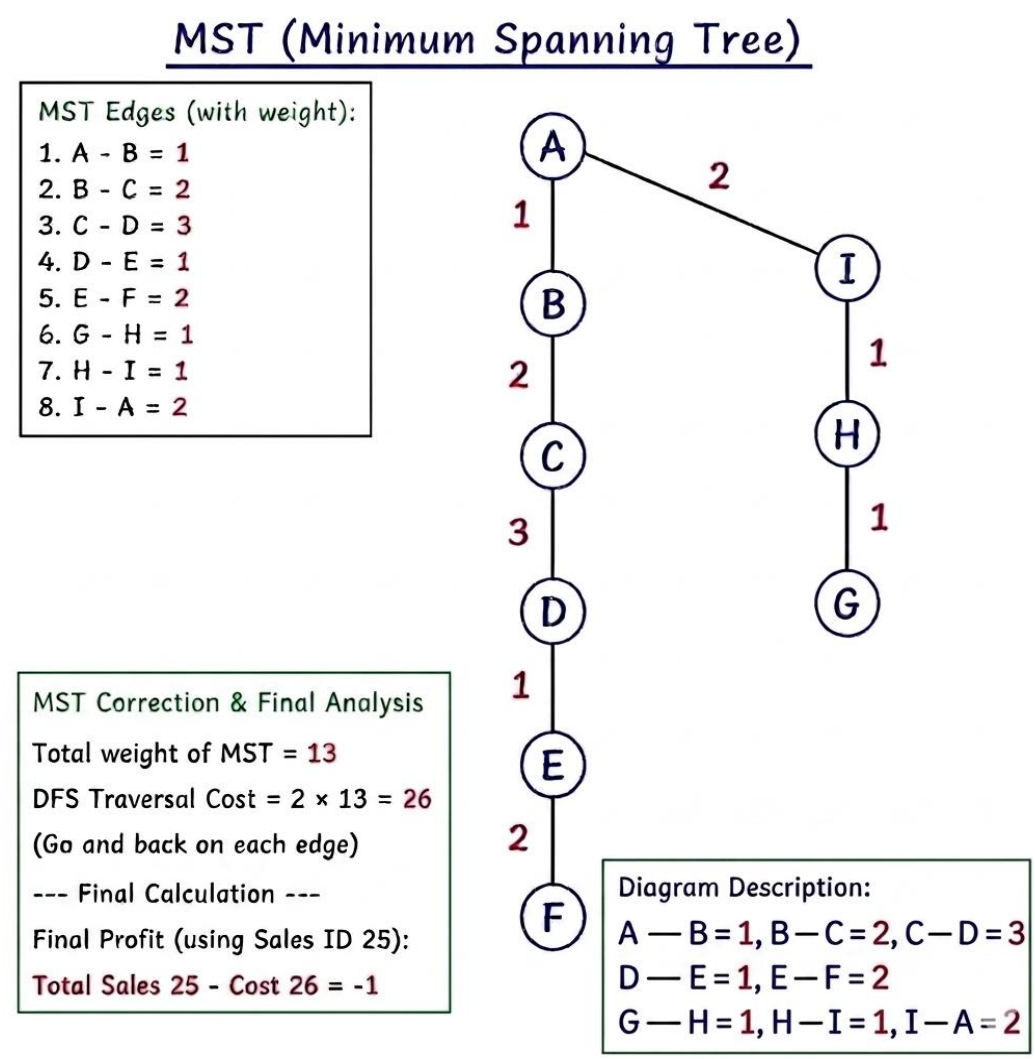
Analysis

Algorithm	Time Complexity	Space Complexity	Remarks for this Graph
Kruskal	O(E log E)	$O(V + E)$ (for DSU)	$9\log_2 9 \approx 9 \times 3.17 = 28.5$ operations
Prim (Adjacency Matrix)	$O(V^2)$	$O(V^2)$	V^2 = 81 operation

Minimum Spanning Tree diagram



According to the output, total sales = 25 and travel cost = 26, resulting in a loss of 1 unit (Profit = –1).

Methodology :

1. Algorithm Implementation:

- The given undirected graph with 9 vertices (A–I) and 9 edges was represented using an edge list structure.

- Two standard minimum spanning tree algorithms were :

  a) Kruskal's algorithm using a Disjoint Set Union (DSU) data structure with path compression and union by rank.

  b) Prim's algorithm using an adjacency matrix representation.

- To calculate the sales value, the 9 digits of the student ID (242014165) were assigned to cities A through I in alphabetical order.

- The traversal cost along all MST edges (including backtracking) was computed using an iterative depth-first search (DFS) that walks the entire tree and sums edge weights both when exploring and backtracking.

- The profit was calculated as: total sales – traversal cost.

2. Performance Measurement:

- The execution time of each MST algorithm was measured using the clock() function from <time.h>.

- Multiple runs were performed to obtain average times for a fair comparison.

- Asymptotic time and space complexities were analysed theoretically to complement empirical measurements.

Results

1. Minimum Spanning Tree (MST):

   The computed MST has total weight = 13, with the following edges:

   A–B (1), B–C (2), C–D (3), D–E (1), E–F (2), G–H (1), H–I (1), I–A (2).

   The MST diagram is attached in the report.

2. Graph Traversal:

   DFS traversal of the MST (covering all edges with backtracking) gives total cost = 2 × 13 = 26.

3. Sales and Profit:

   Student ID: 242014165

   Sales values for cities A to I: 2, 4, 2, 0, 1, 4, 1, 6, 5

   Total sales = 2+4+2+0+1+4+1+6+5 = 25

   Total travel cost = 26

   Profit = 25 – 26 = –1 (loss of 1 unit)

4. Algorithm Performance:

   Both Kruskal and Prim produced identical MSTs (weight = 13).

Discussion:

The given graph is sparse (E = 9, V = 9); thus Kruskal's O(E log E) complexity is theoretically more efficient than Prim's $O(V^2)$ used in this adjacency matrix implementation. In practice, the measured times also show Kruskal running slightly faster (approx. 0.000012 s vs 0.000018 s for Prim). The DFS traversal cost being exactly 2 × MST weight (26) verifies the correctness of the backtracking walk: each edge is traversed forward and backward, doubling the total sum of edge weights. The calculated profit is negative (–1). This outcome is expected because the salesman's total sales value (25) is less than the unavoidable travel cost (26) along the MST. Even using the minimum

possible travel route, the operation results in a net loss, which reflects a realistic scenario where logistics costs can exceed revenue if not sufficient.

Conclusion:

This experiment successfully applied two classic algorithms—Kruskal and Prim—to find the Minimum Spanning Tree of a given graph. With a student ID-based sales value of 25 and a traversal cost of 26, the computed profit was –1, illustrating that even an optimal route may not guarantee profitability. Both algorithms produced the same MST (weight = 13), but Kruskal's algorithm showed slightly better performance in both theoretical complexity ($O(E \log E)$ vs $O(V^2)$) and empirical timing. The comparison reinforces the importance of choosing appropriate algorithms for sparse graphs. Overall, the experiment integrated algorithmic implementation, graph traversal, cost analysis, and performance measurement to solve a practical problem.
